Chapter 1

Model-independently calibrating the luminosity correlations of GRBs using deep learning

1.1 Introduction

The accelerating expansion of the universe is first found from the fact that the luminosity of type Ia supernovae (SNe Ia) is dimmer than expected [?]. This led to the discovery of Dark energy [?]. One of the few ways to measure properties of dark energy is to extend the Hubble Diagram(HD) to high redshift. The only way to extend HD to higher redshift is to Gamma Ray Burts (GRB). GRB have been found to be reasonably good standard candles in the usual sense that light curve and/or spectral properties are correlated to the luminosity, exactly as for Cepheids and supernovae, then simple measurements can be used to infer their luminosities and hence distances. The default expectation is the simplest model for the Dark Energy, where it does not change in time. This can be parametrized with the equation of state of the Dark Energy. The concordance case has w=-1 at all times, and this is the expectation of Einstein's cosmological constant, or if the Dark Energy arises from vacuum energy. Given the strong results from supernovae for redshifts of less than 1, the frontier has now been pushed to asking the question of whether the value of w changes with time (and redshift).

The best way to measure properties of the Dark Energy seems to be to measure the expansion history of our Universe and place significant constraints on models of the Universe. Hubble diagram can be used to measure it. The Hubble diagram (HD) is a plot of distance versus redshift, with the slope giving the expansion history of our Universe. been proposed to determine the distances and redshifts of two thousand supernovae per year out to redshift 1.7 with exquisite accuracy. The default expectation is the simplest model for the Dark Energy, where it does not change in time. This can be parameterized with the equation of state of the Dark Energy. The best way to measure whether dark energy changed with respect to redshift, is to measure it over wide range of redshifts, but supernovaes cannot be detected above 1.7 even with modern satelites. But GRBs offer means extend HD over redshift > 6. The reason is that GRBs are visible across much larger distances than

supernovae.

GRBs are now known to have several light curve and spectral properties from which the luminosity of the burst can be calculated (once calibrated), and these make GRBs into 'standard candles'.

1.2 Literature Survey

The first work on luminosity correlation of GRBs was done by [?]. [?] shows that not all luminosity correlations are applicable across all redshifts. [?] prooves otherwise. [?] shows that is not true. [?] have model independently verified this using deep learning.

1.3 Observational Data

1.3.1 GRB

The GRB dataset we use is from [?]. In Table 1, we list the variables of 116 GRBs that we use in fitting luminosity correlations

1.3.2 Pantheon

Pantheon compilation [?] is the combined sample of SNe Ia discovered from different surveys to form the largest sample consisting of total of 1048 SNe Ia raning from 0.01 < z < 2.3.

1.3.3 Union

The updated supernova Union2.1[?] compilation of 580 SNe is available at http://supernova.lbl.gov/Union

1.4 Methodology

1.4.1 Gaussian Processes

1.4.2 Reccurent Neural Networks

to be written...

1.5 Reconstruction and calibration of distance modulus using Gaussian Processes

We first use Gaussian processes to reconstruct $\mu-z$ relation from pantheon data. Gaussian processes can construct function without involving any model assumption. The Gaussian processes only depend on the covariance function k(x, x'), which characterizes the correlation between the function value at x to that at x'. There are many covariance functions available, but any covariance function

should be positive definite and monotonously decreasing with the increment of distance between x and x'. Here we use the following kernel

$$k(x, x') = ConstantKernel() + 1.0 * DotProduct(1) * *0.1 + 1.0 * WhiteKernel(1)$$

$$\tag{1.1}$$

Our kernel (??) is a sum of linear, constant and whitekernels. Linear Kernel with exponent is used to capture relation in the data, constant kernel is used as scale magnitude and white kernel explains the noise in the input.

1.5.1 Training

We optimize the hyper-parameters of kernels by maximizing the marginal likelihood marginalized over function values f at the whole locations X. We use the publicly available python package sklearn[?] to reconstruct distance modulus as a function of redshift. The results are plotted in (??). The posterior samples drawn from kernel is shown in (??) In the range where data points are sparse, the uncertainty of the reconstructed function is large. While training GP numerical issues are common to occur, hence we set $\alpha = 0.3$ and standardize the distance modulus before training. We also restart optimizer 100 times, parameters sampled log-uniform randomly from the space of allowed range.

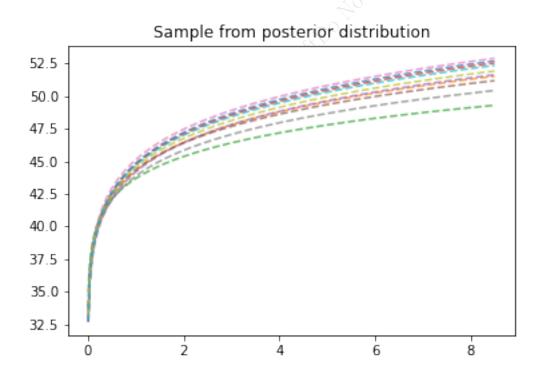

Figure 1.1: Posterior samples drawn from GP

The error bars with predictions are shown below Log Marginal Likelihood = -20.3The coefficient of determination $R^2 = 0.9951$

reconstruction of distance moduli from Pantheon data using Gaussian p

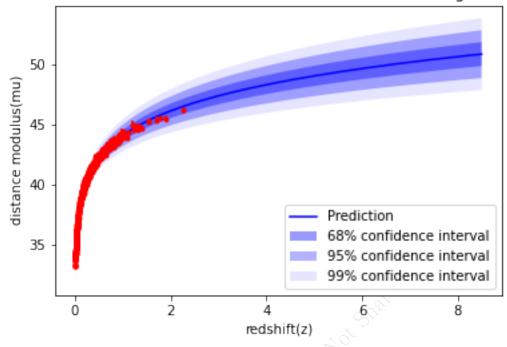

Figure 1.2: The reconstruction of distance moduli from Pantheon data set using GP. The red dots with 1σ error bars are the Pantheon data points. The light-blue dots are the central values of reconstruction. The shaded regions are the 1σ , 2σ and 3σ uncertainties.

1.5.2 Testing redshift dependence of luminosity correlations

The luminosity relations are connections between measurable parameters of the light curves and/or spectra with the GRB luminosity. Specifically, I will be using the power law relationships between explained below. This section will discuss the calibration of all six relations. The calibration will essentially be a fit on a log-log plot of the luminosity indicator versus the luminosity. For this calibration process, the burst's luminosity distance must be known to convert Pholo to L (or Sholo to Egamma) and this is known only for bursts with measured redshifts. However, an important point is that the conversion from the observed redshift to a luminosity distance is done by machine learning model. The observed luminosity indicators will have different values from those that would be observed in the rest frame of the GRB. That is, the light curves and spectra seen by Earth-orbiting satellites suffer time-dilation and redshift. The physical connection between the indicators and the luminosity is in the GRB rest frame, so we must take our observed indicators and correct them to the rest frame of the GRB. For the two times (Tlag and TRT), the observed quantities must be divided by 1+z to correct for time dilation. The observed V value varies as the inverse of the time stretching, so our measured value must be multiplied by 1 + z to correct to the GRB rest frame. The observed Epeak value must be multiplied by 1 + z to correct for the redshift of the spectrum. The number of peaks in the light curve is defined in such a way as to have no z dependance. The dilation and redshift effects on thetajet and Egamma, iso have already been corrected in equations 1 and 2. A possibly substantial problem for the Tlag, V, and TRT relations is that we are in practice limited to the available energy bands (c.f. Table 5) whereas these correspond to different energy bands in the GRB reference frame. Ideally, we would want to measure these indicators in observed energy bands that correspond to some consistent band in the GRB frame

- 1. Lag versus Luminosity $(T_{lag} L)$
- 2. Variability versus Luminosity (V L)
- 3. E_{peak} versus Luminosity $(E_{peak} L)$
- 4. E_{peak} versus E_{γ} $(E_{peak} E_{\gamma})$
- 5. T_{RT} versus Luminosity $(T_{RT} L)$
- 6. E_{peak} versus E_{iso} $(E_{peak} E_{iso})$

$$\log \frac{L}{\text{erg s}^{-1}} = a_1 + b_1 \log \frac{\tau_{\text{lag},i}}{0.1s},\tag{1.2}$$

$$\log \frac{L}{\text{erg s}^{-1}} = a_2 + b_2 \log \frac{V_i}{0.02},\tag{1.3}$$

$$\log \frac{L}{\text{erg s}^{-1}} = a_3 + b_3 \log \frac{E_{p,i}}{300 \text{keV}}$$
 (1.4)

$$\log \frac{E_{\gamma}}{\text{erg}} = a_4 + b_4 \log \frac{E_{p,i}}{300 \text{keV}},\tag{1.5}$$

$$\log \frac{L}{\text{erg s}} = a_5 + b_5 \log \frac{\tau_{\text{RT},i}}{0.1 \text{ s}},\tag{1.6}$$

$$\log \frac{E_{\rm iso}}{\rm erg} = a_6 + b_6 \log \frac{E_{p,i}}{300 \rm keV} \tag{1.7}$$

Assuming that GRBs radiate isotropically, the isotropic equivalent luminosity can be derived from the bolometric peak flux P_{bolo} by (Schaefer 2007)

$$L = 4\pi d_L^2 P_{\text{bolo}} ,$$

where d_L is the luminosity distance of GRB, which can be obtained from the reconstructed distance moduli of Pantheon presented in section B with the relation

$$\mu = 5\log\frac{d_L}{\text{Mpc}} + 25.$$

Hence, the uncertainty of L propagates from the uncertainties of P_{bolo} and d_L . The isotropic equivalent energy E_{iso} can be obtained from the bolometric fluence S_{bolo} by

$$E_{\rm iso} = 4\pi d_L^2 S_{\rm bolo} (1+z)^{-1},$$

the uncertainty of E_{iso} propagates from the uncertainties of S_{bolo} and d_L . If on the other hand, GRBs radiate in two symmetric beams, then we can define the collimation-corrected energy E_{γ} as

$$E_{\gamma} \equiv E_{\rm iso} F_{\rm beam}$$
,

Correlation	sample	N	a	$a_e rr$	b	$b_e rr$	σ	σ_{int}

Table 1.1: A test caption

where $F_{\rm beam} \equiv 1 - \cos \theta_{\rm jet}$ is the beaming factor, $\theta_{\rm jet}$ is the jet opening angle. The uncertainty of E_{γ} propagates from the uncertainties of $E_{\rm iso~and}$ $F_{\rm beam}$.

In order to test if the correlations discussed in the above section vary with redshift, we divide the GRB samples into two subsamples corresponding to the following redshift bins: the low-z sample $(z \le 1.4)$ which consists of 50 GRBs, and the high-z sample (z > 1.4) which consists of 66 GRBs. We investigate the redshift dependence of luminosity correlations for this two subsamples, as well as for the full GRBs sample. To fit the six luminosity correlations, we apply the D'Agostini's liklihood[?]

$$\mathcal{L}\left(\sigma_{\mathrm{int}}, a, b\right) \propto \prod_{i} \frac{1}{\sqrt{\sigma_{\mathrm{int}}^{2} + \sigma_{yi}^{2} + b^{2} \sigma_{xi}^{2}}} \times \exp\left[-\frac{\left(y_{i} - a - bx_{i}\right)^{2}}{2\left(\sigma_{\mathrm{int}}^{2} + \sigma_{yi}^{2} + b^{2} \sigma_{xi}^{2}\right)}\right]$$

For each correlation and each redshift bin, By maximizing this joint likelihood function, we can derive the best-fitting parameters a, b and the intrinsic scatter σ_{int} , where the intrinsic scatter σ_{int} denotes any other unknown errors except for the measurement errors. The results of the fits and the number of GRBs used in each fit are summarized in (??).

We perform a Markov Chain Monte Carlo analysis to calculate the posterior probability density function (PDF) of parameter space. We assume a flat prior on all the free parameters and limit $\sigma_{\rm int} > 0$. Note that not all GRBs can be used to analyze each luminosity correlation, because not all the necessary quantities are measurable for some GRBs. For example, GRBs without measurement of the spectrum lag can not used in the $\tau_{\rm lag} - L$ analysis. Hence, we present the best-fitting parameters, together with the number of available GRBs in each fitting in Table 1 In Figure 5 we plot all the six luminosity correlations in logarithmic coordinates. Low- z and high- z GRBs are represented by blue and red dots with the error bars denoting 1σ uncertainties. The blue line, red line and black line stand for the best-fitting results for low- z GRBs, high- z GRBs and all- z GRBs, respectively. The 1σ and 2σ contours and the PDFs for parameter space are plotted in Figure 6

As shown in Table 1 low- z GRBs have a smaller intercept, but a sharper slope than high- z

GRBs for all the six luminosity correlations. All- z GRBs have the parameter values between that of low- z and high- z subsamples. For the intrinsic scatter, low- z GRBs have larger value than high- z GRBs, and the E_p-E_γ relation has the smallest intrinsic scatter hence we can only obtain its upper limit. The V-L relation has the largest intrinsic scatter, thus it can not be fitted well with a simple line, which is legible in Figure [5 In Figure 6 the contours in the (a,b) plane indicate that the E_p-E_γ relation of low- z GRBs is consistent with that of high- z GRBs at 1σ confidence level. For the rest luminosity correlations, however, the intercepts and slopes for low- z GRBs differ from that of high- z GRBs at more than 2σ confidence level.

1.5.3 Calibrating distance modulus from $E_{peak} - E_{qamma}$ relation

Having luminosity correlations calibrated, we can conversely using these correlations to calibrate the distance of GRBs, and further use GRBs to constrain cosmological models. Since our calibration of luminosity correlations is independent of cosmological model, the circularity problem is avoided. As we have seen, the $E_p - E_{\gamma}$ relation is not significantly evolving with redshift, so we use this relation to calibrate the distance of GRBs. Due to that the TABLE 1

1.5.4 Constraints on the dark energy

Luminosity distance can be written as

$$d_L = c(1+z) \int_0^z \frac{1}{H(z)} dz$$
 (1.8)

For flat Λ CDM, H(z) can be written as

$$H(z) = H_0 \sqrt{\Omega_M (1+z)^2 + 1 - \Omega_M}$$
(1.9)

We use emcee[?] to fit the dark energy equation. With the Pantheon dataset, the matter density of the flat Λ CDM model is constrained to be $\Omega_M = 0.278 \pm 0.007$. With 24 long GRBs alone, the matter density is constrained to be $\Omega_M = 0.307 \pm 0.065$. It indicates that the Hubble diagram in high redshift is consistent with the Λ CDM model

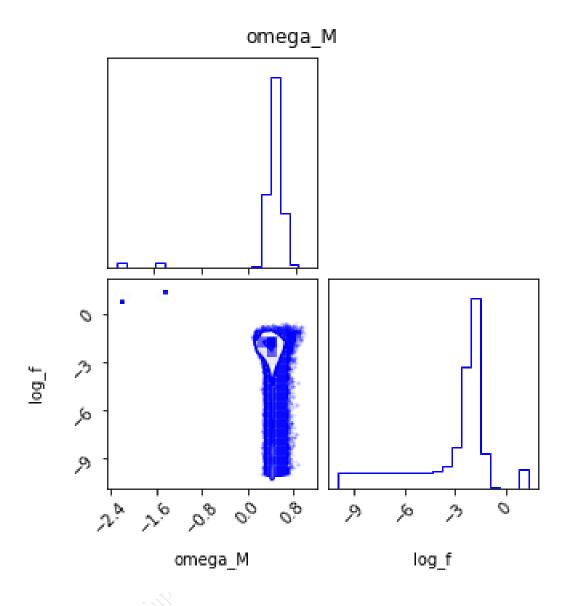

Figure 1.5: GRB Hubble Diagram

1.6 Reconstruction and calibration of distance modulus using Deep Learning

We construct the RNN+BNN network and train it with the package TensorFlow2[?]. For clarity, we present the corresponding hyperparameters in Figure 1 and list the steps to reconstruct data with our network as follow: (a) Data processing. The scale of data has an effect on training. Hence, we normalize the distance moduli of the sorted Pantheon data and re-arrange $\mu-z$ as sequences with the step number t = 4. (b) Building RNN. We build RNN with three layers, i.e. an input layer, a hidden layer and an output layer as described in Figure 1. The first two layers are constructed with the LSTM cells of 100 neurons. The redshifts $z_{< t>}$ and the corresponding distance moduli $\mu_{< t>}$ are the input and output vectors, respectively. We employ the Adam optimizer to minimize the cost

function MSE and train the network 1000 times. (c) Building BNN. We set the dropout rate to 0 in the input layer to avoid the lost of information, and to 0.2 in the second layer as well as the output layer (Bonjean 2020; Mangena et al. 2020). We execute the trained network 1000 times to obtain the distribution of distance moduli

1.6.1 Training

We train the neural network using pantheon data. The pantheon data is split into train and test data in equal size randomly. 512 datapoints are used for training and remaining for testing. The network architecture is described in previous section. We use meansquared error loss and adam optimizer, with early stopping technique to prevent overfitting. Dropout technique with $dropout_rate = 0.2$. The hyperparameters used are $batch_size = 10$, $learning_rate = 1e-3$, patience = 5.

Chapter 2

Model Comparison of Dark Energy models Using Deep Network

2.1 Introduction

2.1.1 Dark energy models

 Λ CDM

 Ω CDM

CPL

2.2 Literature Survey

Given a specific model and a set Then a question of model choice naturally arises with the development of various dark energy models. A variety of methods such as the F-test, Akaike information criterion (AIC) (Penny et al. 2006), Mallows C_p , Bayesian information criterion (BIC) (Penny et al. 2006), minimum description length (MDL) (Rissanen 1978), and Bayesian model averaging have been proposed to select a good or useful model in light of observations. MacKay 1992 strongly recommends using Bayesian evidence to assign preferences to alternative models since the evidence is the Bayesian's transportable quantity between models, and the popular easyto-use AIC and BIC as well as MDL methods are all approximations to the Bayesian evidence (Penny et al. 2006). The Bayesian evidence for model selection has been applied to the study of cosmology for a long time (Trotta 2008; Martin et al. 2011; Lonappan et al. 2018; Basilakos et al. 2018), and recently a detailed study of Bayesian evidence for a large class of cosmological models taking into account around 21 different dark energy models has been performed by Lonappan et al. 2018. Although Bayesian evidence remains the preferred method compared with information criterions, a full Bayesian inference for model selection is very computationally expensive and often suffers from multi-modal posteriors and parameter degeneracies, which lead to a large time consumption to obtain the final result.

2.3 Observational Data

2.3.1 Union2.1

The observations are from the Union2.1 compilation [?] which contains 580 SNeIa, and x_{obs} , real signify the measured distance moduli, Σ_{obs} represents the covariance of the distance moduli with systematics.

2.4 Methodology

- 2.4.1 VAE
- 2.4.2 GAN
- 2.4.3 VAEGAN

To be written

2.5 Test on toy model

This section creates two toy models to test the data reconstruction and model comparison ability of the network.

Model 1,

$$y = Az^{2} + (-A + B)z + C$$
 where, $A \sim \mathcal{N}(-4, 0.1), B \sim \mathcal{N}(0, 0.01), C \sim \mathcal{N}(0, 0.1)$

Model 2,

$$y = A\sin(\omega z) + C$$
 where, $A \sim \mathcal{N}(1, 0.1), \omega \sim \mathcal{N}(\pi, 0.01), C \sim \mathcal{N}(0, 0.1)$

Model 1 and Model 2 have similar distributions as shown in Figure 2 Given the observations $\boldsymbol{x}_{\text{obs,real}}$ which are generated by the underlying model $y_{\text{true}} = -3.5z^2 + 3.6z - 0.1$ on $\boldsymbol{z}_{\text{obs}} = \{z_1, z_2, \cdots, z_{580}\}$ with an error matrix Σ_{obs} , we would like to fit the two toy models to the observations to tell which one is most probable to be the true model, and interpolate the data with the model at $\boldsymbol{z}^* = \{z_1^*, \cdots, z_M^*\}$, for example, \boldsymbol{z}^* even staying in the interval [0, 1] with M = 1468.

First we concatenate and sort z and z^* , and call the new one z. Then sample $\{A_i, B_i, C_i, \omega_i\}$ from the priors of the toy models and generate the training samples $x_i = M_k (z \mid A_i, B_i, C_i, \omega_i)$ (Note that which set of parameters should be used depends on the toy model). Here 12800 samples for each model are generated as the training dataset. Finally, the training set $\{x\}_{i=1}^{25600}$ together with the observation error Σ_{obs} is fed into the network. Once the training converges, one can put the observations $x_{obs,real}$ into the network to tell which toy model is most probable and get the interpolation, see Figure 3 In this task, the discriminator has a classification accuracy of almost 1. It assigns a probability of 97% to the parabolic model (Model 1), which is indeed the case.

2.6 Dark enrgy models

We study the model comparison problem among three dark energy models: $(1)\omega(z) = -1(\Lambda \text{CDM}); (2)$ $\omega(z) = \omega_{DE}(\omega \text{CDM}); (3)\omega(z) = \omega_0 + \omega_a \frac{z}{1+z}$ (CPL), given a set of observations of distance moduli at different redshifts. The expansion rate of a spatially flat FRW universe is determined by the matter and dark energy,

$$H^{2}(z) = H_{0}^{2} \left\{ \Omega_{m0}(1+z)^{3} + (1 - \Omega_{m0}) \exp \left[3 \int \frac{1 + \omega(z')}{1 + z'} dz' \right] \right\}$$

The luminosity distance is closely related to the Hubble expansion rate (Eq.12), and the distance modulus is given by Eq13

$$D_L(z) = c(1+z) \int_0^z dz' \frac{1}{H(z')}$$

$$\mu(z) = 5 \log_{10} D_L(z) + 25$$

For each dark energy model, 12800 samples are generated at the redshift $z = \text{sort}\{z_{\text{obs}}, z^*\}$, given the priors of the parameters as,

$$\Omega_{m0} \sim \mathcal{U}(0.1, 0.9)$$
 $H_0 \sim \mathcal{U}(50, 90)$
 $\omega_{DE} \sim \mathcal{U}(-1.8, -0.4)$
 $\omega_0 \sim \mathcal{U}(-1.9, -0.4)$
 $\omega_a \sim \mathcal{U}(-4.0, 4.0)$

 z^* has 1468 elements evenly located in the interval, $[0.8 \min(z_{obs}), 1.2 \max(z_{obs})]$. The 12800 × 3 samples

Chapter 3

Photometric redshift estimation using Symbolic Regression

3.1 Introduction

Large scale structure cosmology and extragalactic astronomy rely heavily on accurate estimate of the redshift of objects under study. For example the reconstruction of the two point correlation function for galaxies is critical to understand the history of structure formation in the Universe and probe theories beyond Λ CDM. Unfortunately it is a very time consuming and expensive task to obtain spectroscopic data for the millions of observed galaxies. It has therefore long been a challenge to estimate the redshift of galaxies using the much easier to obtain photometric data.

3.2 Literature Survey

The estimation of redshifts from photometric data has been an industry for some years in astronomy culminating in the production of MegaZ-LRG [1], a database of photometric redshifts of 1 million luminous red galaxies in the range 0.4 < z < 0.7 and the 2MPZ database[2] for z < 0.3. The aim is to model the spectroscopic redshift using photometric redshift estimator, $z_{phot}(u, g, r, i, z)$, where u, g, r, i, z are the standard photometric magnitudes. There have been two main approaches to the problem: template based methods ([3] [4] [5] [6] [7] [8] [9] [10] [11] [12]) and machine learning/empirical methods ([13] [14] [15] [16] [17] [18] [19]). For comparisons of the various codes see ([20] [21] [22]). One of the best performing codes is ANNz[13] which is based on artificial neural networks and was used in creating the MegaZ and 2MPZ databases.

3.3 Observation Data

The data in this study are drawn from SDSS Data Release 17 [23]. The SDSS I-III uses a 4 meter telescope at Apache Point Observatory in New Mexico and has CCD wide field photometry in 5 bands (u, g, r, i, z [24] [25]), and an expansive spectroscopic follow up program [26] covering π radians of the northern sky. The SDSS collaboration has obtained approximately 2 million galaxy

spectra using dual fiberfed spectrographs. An automated photometric pipeline performed object classification to a magnitude of $r \approx 22$ and measured photometric properties of more than 100 million galaxies. The complete data sample, and many derived catalogs such as the photometric redshift estimates, are publicly available through the CasJobs server[27] ¹.

3.3.1 SDSS DR17 photometry

The SDSS is well suited to the analysis presented in this paper due to the enormous number of photometrically selected galaxies with spectroscopic redshifts to use as training, cross-validation and test samples. We select 1,958,727 galaxies from CasJobs with both spectroscopic redshifts and photometric properties. In detail we run the following MySQL query in the DR17 schema:

```
-- Goto http://skyserver.sdss.org/casjobs/, create an account run the following sql query
-- http://skyserver.sdss.org/dr17/SearchTools/sql cannot be used to bulk data (only 500000)
-- SQL geury
-- =======
-- only select galaxies that have a photometric galaxy classification type = 3,
-- and spectscopic redshifts, r band magnitudes, -- and radii greater than 0
-- make a magnitude error cut of < 0.3 (in all 5 bands) to ensure that you don't get junk obje

We apply the SDSS extinction corrections to the psf and fiber magnitudes, and further only select galaxies that have a photometric galaxy classification type = 3, have spectroscopic redshifts, r band magnitudes, and radii greater than zero. This reduces the sample size to 1,922,231 galaxies.

3.4 Methodology

3.4.1 Symbolic Regression

Symbolic regression (SR) is a novel machine-learning technique that approximates the relation between an input and an output through analytic mathematical formulae ([?] [?] [?] [?] [?] [?] [?]). The advantage of using SR over other ML regression models like RF or deep neural networks is that it provides analytic expressions that can be readily generalized and that facilitate understanding the underlying physics. Furthermore, SR is shown to outperform other ML models when the size of dataset is small[?].

3.5 Photometric redshift estimation

For our symbolic regression we rely on PySR[28]. It uses genetic programming to find a symbolic expression for a numerically defined function in terms of pre-defined variables. The population consists of symbolic expressions, visualized as a tree and consisting of nodes with an operator function or an operand. We use the operators for addition, subtraction, multiplication. The tree population evolves when new individuals are created and old ones are discarded. To breed the next generation, several mutation operators can be applied, for instance exchanging, adding or deleting nodes of the parent tree. The hyperparameter populations = 30 defines the number of populations and is per default set to the number of processors used (procs). The number of individuals per populations is given by npop = 1000. As the figure of merit for the PySR algorithm we take the mean squared

error between the data points $t_i(x,z|\theta)$ and the functional description g_i

$$MSE = \frac{1}{n} \sum_{i=1}^{n} (g_i(x) - t_i(x, z|\theta))$$
(3.1)

and balance it with the function's complexity, defined as

$$complexity = \#nodes$$
 (3.2)

For the PySR score value, not to be confused with the statistics version of the optimal observable defined in, the parameter parsimony balances the two conditions,

$$score = \frac{MSE}{baseline} + parsimony \times complexity \tag{3.3}$$

The hyperparameter maxsize restricts the complexity to a maximum value. We adjust this value depending on the difficulty of the regression task taking 50 as a starting point and increase (decrease) it if the required complexity is larger (smaller). Additionally we can restrict the complexity of specific operators to obtain a more readable result. We set the maximal complexity of square to 5 and cube to 3. Note that in some instances we choose to not extract the score, but the score scaled by a constant, to improve the numerics with an order-one function. Simulated annealing allows us to search for a global optimum in a high-dimensional space while preventing the algorithm from being stuck in a local optimum. A mutation is accepted with the probability

$$p = exp\left(-\frac{score_{new} - score_{old}}{alpha \times T}\right)$$
(3.4)

The parameter T is referred to as temperature. It linearly decreases with each cycle or generation, starting with 1 in the first cycle and 0 in the last. The hyperparameter ncyclesperiterations = 200 sets the amount of cycles. We choose alpha = 1. If the new function describes the data better than the reference tree, $score_{new}\ score_{old}$, the exponent has a positive sign and the new function is accepted. If the new sore is larger than the old score, the acceptance of the new function is given by p and hence exponentially suppressed. We use this default PySR form for our simple example and discuss a bettersuited form for our application in Sec. 3. The hyperparameter niterations = 300 defines the number of iterations of a full simulated annealing process. After each iteration the best formulas are compared to the hall of fame (HoF). For each complexity the best equation is chosen and saved in the output file. An equation of higher complexity is only added if its MSE is smaller than for previous formulas. Equations from different populations or the hall of fame can migrate to other populations. This process is affected by the parameters fractionReplaced = 0.5 and fractionReplacedHof = 0.2.
